Abstract
Aim and Objectives: To measure, calculate, find out variations and finally compare the pattern of talar articular facets of different human calcanei.

Materials and Methods: 50 adult human calcanei were obtained irrespective of age and sex and evaluated one by one. Three types of calcaneus that has distinct talar facets as Types A, B and C and sub types were defined.

Results: The study reveals the following results;
Out of 50 calcanei 13 were of Type A (26%) 37 were of Type B (74%) and None were of Type C. The mean intersecting angle of Type A calcaneum is 121.50 and The mean intersecting angle of Type B calcaneum is 151.60

Conclusion: This study reveals that the talar facet configuration of calcanei and angle between the anterior and middle facet influences the stability of the subtalar joint.

Key words- Calcaneus, facets, subtalar joint.

Introduction
The calcaneus is the longest and the largest of the tarsal bone. It articulates with the overlying talus to form the talocalcaneal joint which together with talocalcaneonaviculuar joint are clinically referred to as the subtalar joint [1], where the important movements of inversion and eversion of the foot occur.

There are three facets over superior surface of talocalcaneal joint: anterior talar facet, middle talar facet and posterior talar facet [2].

The middle third of the superior surface of the calcaneum carries the posterior talar facet for the articulation with the body of the talus. In most textbooks of Anatomy descriptions of the posterior talar facet on the middle third of the dorsal surface of the calcaneus are similar [3-5]. However, descriptions of the facet for the head of the talus are at variance. In the anterior third of the calcaneus, distal and medial to the sulcus calcanei, an articular area covers the sustentaculum tali, this facet articulates with the head of the talus, and may be divided in about half the cases by a non articular zone creating middle and anterior talar facets, the incidence of which varies with race and sex [6].

Changes in the human foot associated with the evolution of bipedalism involved the elevation of the calcaneus which increased the inclination of the subtalar joint axis to approximately 42°. This elevation was crucial for the formation of the longitudinal arch. The sustentaculum tali is at the ‘apex’ of the longitudinal arch and thus occupies a key position in the subtalar joint. It functions as a bracket that supports the talar head and is responsible for transmission of force towards the lateral arch[7-9]. Variations in the articular facets of the sustentaculum tali have been described by many authors. Although these researchers use slightly different classificatory schemes, 3 distinct facet types are generally recognised:

1) 1 long continuous facet
2) 2 separate facets and
3) Only one continuous facet
These facet configurations are present in fetal calcanei and are not developmental responses to physical activities [9]. Most researchers view these differences in facet configuration as anatomical variations of no functional significance. Bruckner [10] in contrast, argues that the 2-facet configuration is more stable than the others. The 2-facet configuration is typically associated with a higher angled subtalar joint axis and a sharper intersecting angle, i.e. “Critical angle of Gissane” of the anterior and medial facets [10]. These characteristics, in conjunction with the posterior talocalcaneal facet, cause the talus to sit on an ‘osseous tripod’ and prevent excess motion of the talar head. A 2-facet configuration is more stable, there should be less evidence of pathological changes associated with this configuration. Unstable joints are more likely to suffer trauma, accidents, or other biomechanical stress as a result of uneven weight distribution [6-8].

Using parameters such as degree of separation, fusion and shape, some researches have described types and preponderance of articular facets. Morphometric values of calcanei are important for the science of anatomy, treatment and diagnosis procedures on orthopedic surgery, kinesiology, physical treatment and rehabilitation sections. The racial and individual differences of the anatomic construction of the calcanei play a key role on static and kinetic dynamic on the foot. During the treatment period of the congenital club foot, talocalcaneal coalition, severe pronation cases, valgus deformities, subtalar instability and development of subtalar implants talus-calcaneus with each other and other bones of foot should well defined [9,11,12]. Calcaneal lengthening osteotomy, as popularized by Mosca, is extra-articular, with its site being the interval between the anterior and middle calcaneal facets. For individuals without a distinct anterior and middle facet, the subtalar joint must be violated to perform this operation [13]. The detailed calcaneal anatomy shall facilitate the alternatives of treatment procedures.

Materials and Methods
Fifty adult human calcanei were obtained from the Department of Anatomy, MGM Medical College, Kamothe, Navi Mumbai and MGM Medical college, Aurangabad irrespective of age and sex and evaluated one by one. The study was carried with naked eyes and hand lens in broad day light and distance between the facets were measured with a vernier calliper.

Classification of calcaneum
According to Mujde.U, et al [2], three types of calcaneii that has distinct talar facets as Types A, B and C and sub types were defined.

Type A
On calcaneus, two anterior articular facets.

Type B
Single anterior and middle articular facets fused.

Type C calcaneus
An anterior and posterior articular confluent facet i.e. there is one joint facet (Fig. 3)

Fig. 1- Type A: On calcaneus, two anterior articular facets.

Fig. 2- Type B: Single anterior and middle articular facets fused. Type B is again subdivided into (Fig. 2)
- Type B1: the separation between these two joint facets was not completed. The shape of facet joint was constricted (antero-middle joint facets were constricted).
- Type B2: there was no separation between these two joint facets. There was only one wide smooth facet (unconstricted).

Fig. 3- Single joint facet

Fig. 4- Measuring Degrees of intersecting angles: (a) continuous facet configuration Mean angle 121.5°; (b) 2-facet configuration Mean angle 151.6°.

The angle formed by the intersection of the medial and anterior
facets of the sustentaculum tali, was determined using the following procedure. The calcaneus was placed on its medial side on a piece of paper so that the medial border of the sustentaculum tali facets contacted the paper and the planes of the facets were perpendicular to the surface of the paper. The contour of the facets was traced with a pencil and the angle measured with a protractor (Fig. 4). Repeated observations made on the same series of bones indicated that the average error of this measurement is about 2° [13].

The presence of lipping and osteophytes was determined by visual inspection of the articular surfaces.

Results
The study reveals the following results:

Table I- Showing different types of articular facets of calcanei

Discussion
The joint facets on calcanei which articulate with talus show variations with race and sex. In textbooks, anterior and posterior facets are mentioned separately while the middle one is defined as the continuation of the anterior facet. Although it is necessary to define and appreciate these differences for medical science to make accurate diagnosis and the treatment, there is no detailed knowledge indicating these differences. It is well known that the treatment choices of the complex foot deformity are osteotomy and relaxation of the soft tissue to obtain a painless and functional treatment choices of the complex foot deformity are osteotomy and relaxation of the soft tissue to obtain a painless and functional treatment choices of the complex foot deformity are osteotomy and relaxation of the soft tissue to obtain a painless and functional treatment choices of the complex foot deformity are osteotomy and relaxation of the soft tissue to obtain a painless and functional treatment choices of the complex foot deformity are osteotomy and relaxation of the soft tissue to obtain a painless and functional

Conclusion
The variations in the superior surface of the calcaneus enable the calcanei to be classified according to the number and disposition of the articular facet of the talus. In this study Type B (single anterior and middle facet fused) was 74% with mean intersecting angle of 151.6° and Type A (two anterior facet) 76% with mean intersecting angle of 121.5°.

This study reveals that the talar facet configuration of calcanei and angle between the anterior and middle facet influences the stability of the subtalar joint.

Acknowledgement
We cordially thank our Head of the department, Dr. Aruna Mukherjee, for her extensive support and guidance throughout the study period and we also thank Dr. Narshetty, Dean, MGM Medical College for his great support and permitting us to perform this study.
